**A. General**

**A.1. Stock definition**

Atlantic mackerel (*Scomber scombrus*) occurs on both sides of the North Atlantic and has traditionally been grouped into five spawning components, some of which have been thought to be isolated natal homing populations. Previous studies have provided no evidence of cross-Atlantic migration and no, or weak, support for isolated spawning components within either side of the North Atlantic (Jansen and Gislason, 2013).

ICES currently uses the term “Northeast Atlantic (NEA) mackerel” to define the mackerel present in the area extending from the Iberian peninsula in the south to the northern Norwegian Sea in the north, and Iceland in the west to the western Baltic Sea in east.

In the Northeast Atlantic, mackerel spawn from the Portuguese waters in the south to Iceland in the north and from Hatton Bank in the west to Kattegat in the east. Spawning starts in January/February in Iberian Peninsula waters and ends in July to the northwest of Scotland and in the North Sea (ICES, 2013.a). While spawning varies locally from day to day (Bakken, 1977; Iversen, 1981), it seems to form one large spatio-temporal continuum on the larger scale. However, relatively low levels of spawning in the English and Fair Isle channels separates the main spawning areas in the North Sea from the western areas along the continental shelf edge (Johnson, 1977).

Recent studies on distribution, eggs distribution and abundance and mark–recapture experiments (Reid, 1997; Uriarte and Lucio, 2001; Uriarte *et al.*, 2001) have questioned the limits of previously established stocks and proposed to consider NEA mackerel as one single stock divided into three spawning components. These components are not completely independent but reproductive exchanges occur, and no differences were observed between these components outside the spawning season (Jansen and Gislason, 2013). Despite this lack of complete spatial or temporal separation, NEA mackerel is divided into three distinct entities, namely the Southern, Western and North Sea spawning components (ICES 1977; 2013.a). Catches cannot be allocated specifically to spawning area components on biological grounds, but by convention; catches from...
the Southern and Western components are separated according to the areas in which these are taken:

</tr>
</tbody>
</table>

The Western component is defined as mackerel spawning in the western area (ICES Divisions and Subareas 6, 7, and 8.a, b, d, e). This component currently accounts for ~75% of the entire Northeast Atlantic stock. Similarly, the Southern component (~22%) is defined as mackerel spawning in the southern area (ICES Divisions 8.c and 9.a). Although the North Sea component has been at an extremely low level since the early 1970s, ICES considers that the North Sea component still exists as a discrete unit (~3%). This component spawns in the North Sea and Skagerrak (ICES Subarea 4 and Division 3.aN).

Jansen and Gislason (2013) recently reviewed the concept of spawning components on the basis of spawning and age distribution data. Spawning intensities, proxied by larval abundances, were found to be negatively correlated between the North Sea and Celtic Sea, which indicates that the two spawning components may be connected by substantial straying. This finding was based on unique larvae samples collected before the collapse of North Sea component, thus showing that the exchange is not a recent phenomenon due to the collapse. Furthermore, analyses of old as well as more recent age distributions showed that strong year classes spread into other areas where they spawn as adults (i.e. “twinning”). The authors found that this was in accordance with the lack of solid evidence of stock separation from previous analyses of tagging data, genetics, ectoparasite infections, otolith shapes, and blood phenotypes. Because no method has been able to identify the origin of spawning mackerel unequivocally from any of the traditional spawning components, and in the light of their results, they concluded that straying outweighs spatial segregation. Jansen and Gislason (2013) therefore proposed a new model where the population structure of mackerel was described as a dynamic cline, rather than as connected contingents. Temporal changes in hydrography and mackerel behaviour may affect the steepness of the cline at various locations (Jansen, 2013; Jansen and Gislason, 2013; Jansen et al., 2013).

A.2. Fishery

As a widely distributed and migratory species, NEA Mackerel is exploited over a wide geographic range throughout the year. Significant fisheries extend from the Gulf of Cadiz, along the western and northern Iberian costs, through the Bay of Biscay, S, W and N of the United Kingdom and Ireland, into the northern North Sea and the Norwegian Sea and, in more recent years as far north as 72°N and west into Icelandic and east Greenland waters.

The fishery is international and, as such it is exploited by several nations using a variety of techniques determined by both the national fleet structure and the behaviour of the mackerel. At the onset of the spawning migration, large mackerel shoals move out of the northern North Sea initially to the west before moving south down the west coast of Scotland and Ireland. The timing of this migration is variable but generally occurs around the end of quarter 4 and the start of quarter 1. During this time, they are targeted primarily by Scottish and Irish pelagic trawlers with RSW tanks and also freezer (factory) vessels (primarily Dutch and German). Prior to the onset of this
migration the mackerel are overwintering, relatively static and are targeted by a large Norwegian purse-seine fleet. During summer the mackerel are more widely dispersed as they feed in Northern waters. At this time Russian pelagic freezer trawlers and in more recent times Icelandic, Faroese and Greenlandic pelagic vessels are active. The southern fishery takes place at the start of the spawning season upon completion of the spawning migration. The Spanish fleet is comprised of both bottom and pelagic trawlers and also a large artisanal fleet. There are other smaller scale fisheries such as a Norwegian gillnet fleet and an English handline fleet that operates in the otherwise restricted area known as the Cornwall box.

There exist a number of national and international agreements to control the exploitation of the NEA Mackerel stock. Targeted fishing is prohibited in the North Sea with the purpose of protecting the North Sea stock component which has failed to recover from extremely heavy exploitation during the 1970s. The Cornwall box is an area off the SW coast of England that is a known juvenile area. It supported a very large fishery prior to its introduction in the early 1980s after which the only permitted fishing in this area is by handliners. A number of countries have discard prohibition. Unfortunately, there has been no overarching agreement in the most recent period which would permit control of the overall exploitation and catches have exceeded advice. Since 2015 within the EU a landing obligation comes into force, under this new law all the species managed through TACs and quotas must be landed. Due to its gradual implementation, at the moment it only affects to all the EU pelagic and industrial vessels but by 2019 it is expected to affect all European commercial fisheries.

A.3. Ecosystem and behavioural aspects

A.3.1. Feeding

Post larval mackerel feed on a variety of zooplankton and small fish. They prefer larger prey species over smaller prey (Pepin et al., 1987; Langøy et al., 2006). Feeding patterns vary seasonally, spatially and with size. Mackerel stops feeding almost completely during winter. Main zooplankton prey species in the North Sea are: Copepods (mainly Calanus finmarchicus), euphausiids (mainly Meganyctiphanes norvegica), while primary fish prey species are: sandeel, herring, sprat, and Norway pout (Walsh and Rankine, 1979; Mehl and Westgård, 1983; ICES, 1989; ICES, 1997). In the Norwegian Sea euphausiids, copepods (mainly Calanus finmarchicus and Oithona), Limacina retroversa, Maurolicus muelleri, amphipods, Appendicularia and capelin are the main diet during the summer feeding migration (Langøy et al., 2006; Prokopchuk, 2006; Langøy et al., 2010).

In the North Sea, mackerel and horse mackerel are responsible for virtually all of the predation on 0-group herring as well as a large part of the consumption of 0-group Norway pout and of all ages of sandeel (ICES, 2008a). Mackerel has also fed opportunistically on available NSS herring larvae along the continental shelf coast of Norway (Skaret et al., 2014). This may have a significant impact on the herring larval survival rate, and largely depends upon the degree of overlap in time and space, which can vary from year to year.

Spatial and temporal overlap between NEA mackerel and Norwegian spring-spawning herring in the outskirts or periphery of mackerel distribution (northern Faroese, Icelandic and Jan Mayen waters) may cause increased interspecific competition between mackerel and herring for preferred food such as Calanus finmarchicus (Debes et al., 2012; Langøy et al., 2012; Öskarsson et al., 2012). Mackerel may partly outcompete herring during summer because mackerel are generally larger,
faster, more enduring when migrating and more effective plankton eaters, including a wider food niche (wider diet breadth) than herring (Nøttestad et al., 2012). Mackerel may thus both compete better for preferred zooplankton species and size fractions as well as better utilize smaller plankton species available in the northern part of the Northeast Atlantic Ocean compared with herring.

The mackerel seems to be very opportunistic, and from one year to the next they may exploit any available oceanic areas for feeding purposes (Langøy et al., 2012). A westwards and northwards expansion has been observed in the Nordic Seas in recent years (since 2007), as far as Icelandic and south Greenlandic waters in the west and as far north as Spitzbergen (Nøttestad, 2014). Historically, expansions into Icelandic waters are known to coincide with periods of warm waters (Astthorsson et al., 2012).

The dynamics and environmental drivers of the mackerel summer distribution are not yet uncovered. Surveys in recent years indicate substantial interannual variation and provides hypothesis on relations to temperature and food (Holst and Iversen, 1992; Holst and Iversen, 1999; Gill, et al., 2004; ICES, 2006; ICES, 2007; ICES, 2009). When the mackerel stock is large (as in the recent years) and plankton abundance is low, mackerel has to spread out further to the north and to the west to forage on suitable plankton aggregations. The record high surface temperatures observed in the Nordic Seas during summer in recent years (Hughes et al., 2011; Nøttestad et al., 2012) made this expansion possible and has resulted in an increase in the potential feeding habitat for mackerel (as defined by water temperatures above 6°C).

A.3.2. Spawning

Even though spawning occurs widely on the shelf and shelf edge from the Bay of Biscay to the southern Norwegian Sea, most of the egg production is concentrated in two core spawning areas (Figure A.3.2.1). One elongated area along the shelf break from Spanish and Portuguese waters in January to March, and one around southwest Ireland to the west of Scotland where spawning peaked in April (Beare and Reid, 2002; Iversen, 2002) but the spawning peak has shifted to March in the most recent years. In the central North Sea spawning takes place in May–July.

Spawning activity along the shelf edge has varied to the north and to the south at various times over the decades since the 1980s although the centre of gravity of spawning has remained relatively stable off the southwest of Ireland over this period (Hughes, 2013; Beare and Reid, 2002). In the North Sea there is a westward shift in the main spawning area from the central part of the North Sea in the early 1980s to the western part in recent years (2005 and 2008) (Anon, 2009).

In the recent period (since the 2007 survey) an expansion of the spawning distribution for the western spawning component has been observed (ICES, 2013b). Spawning occurs now further to the west (up to 20° of latitude west) and to the north (up to the southern Norwegian Sea) (ICES, 2013b; Nøttestad et al., 2012; 2013). However, most of the egg production of the western component remains in the traditional spawning grounds, located on the shelf edge in the southwest of Ireland to the west of Scotland. The egg production in the new areas remains marginal. The causes of this geographical expansion of spawning remain unclear, but are suspected to be triggered by the increase in the stock size (i.e. density-dependent space occupation) coupled with changes in the potential spawning habitat linked to environmental conditions (ICES, 2013b). As a consequence of this expansion of spawning to the North, juveniles 0-group mackerel are now found in the Nordic seas (Iceland, Barents sea, ICES 201 3.a).
Figure A.3.2.1. NEA mackerel spawning areas. Upper left: Shaded areas indicate 100 eggs/m² in at least two of the years in the period 1977–1988 (from ICES, 1990). Upper right: Average distribution of mackerel eggs by ICES statistical rectangle in 1992–2007, each map represents a survey between February and August (from Anon, 2009). Lower left: North sea spawning area defined by a daily egg production of at least 50 mackerel eggs per m² of sea surface in any of the years 1980, 1983, 2005 and 2008 (from Anon, 2009)). Lower right: Experimental survey in May 2002 (from Dransfeld et al., 2005)).
Mackerel performs extensive migrations between spawning grounds, feeding grounds and overwintering areas. The migration pattern has changed substantially through time (see Figure A.3.3.1).

Tagging studies (Uriarte and Lucio, 1996; Belikov et al., 1998; Uriarte et al., 2001) have demonstrated that mackerel travel from both the western and southern spawning ground north up into the North Sea and Nordic Seas. The migration can be considered as having two elements;

1) A post-spawning migration from the spawning areas along the western European shelf edge (Uriarte et al., 2001);

2) A pre-spawning migration from feeding grounds in the North and Norwegian Seas (Walsh et al., 1995; Reid et al., 1997). This pre-spawning migration includes shorter or longer halts that sometimes are referred to as overwintering.

Studies of the timing and the routes for the post-spawning feeding migration are limited. Patterns of food and temperature related distributions in the Norwegian Sea in summer are emerging from summer surveys in the Norwegian Sea in 1992 and 2002–2009. However, the big picture of when and where is the thermal preference dominating/subordinate in relation to other activities like feeding, spawning and predator avoidance remains to be drawn.

Swimming speed during migration is related to fish length (Pepin et al., 1988). Tagging has shown that juveniles of the southern/western component do not migrate as far as the adults (Uriarte et al., 2001). The larger fish reaches furthest to the north and west during the feeding migration in summer (Holst and Iversen, 1992; Nøttestad et al., 1999; Anon 2009; ICES, 2009). This effectively results in a spatial gradient in the mean length of the fish measured during the IESSNS (Nøttestad et al., 2012; 2013), with larger mean length in the north and west, and smaller mean length to the southeast. Similarly, the large mackerel also arrive to the feeding areas (observed in eastern Danish waters) before and leave later than small mackerel (Jansen and Gislason, 2011).

When the NEA mackerel return in late summer and autumn from the feeding areas on the European shelf and in the Nordic Seas, they aggregate through autumn and early winter along the continental shelf edge, where they are targeted by commercial trawlers and purse-seiners. Later in winter the commercial fleets and the fisheries-independent bottom-trawl survey find the mackerel further towards the southwest. The path of the migration, as suggested by the location of commercial and survey catches coincides with the location of the relatively warm high saline eastern Atlantic water flowing northeastwards on and along the continental shelf edge, flanked by cooler water masses. The mackerel population is found further upstream in warmer waters as the current cools through winter and this process is associated via climatic variability, with large impacts on the mackerel migration and fisheries (Jansen et al., 2012; Walsh and Martin, 1986; Reid et al., 2003; Walsh et al., 1995; Reid et al., 1997; Reid et al., 2001). However, other factors than temperature preferences are affecting the mackerel behaviour and can in different scenarios have different weights. D’Amours and Castonguay (1992) showed that mackerel from the northern component of the West Atlantic mackerel migrated into Cabot Straight with approximately 4°C in order to get to their spawning grounds. They argued that the fish’s thermal preferences could be subordinate to their reproductive requirements, a point sup-
ported by the fact that this stock always enter the Cabot Straight around the same date (Anon., 1896; Castonguay and Beaulieu, 1993).

There are also indications of variation in spawning time: The Spanish spring fishery in the Bay of Biscay has been occurring earlier each year, and since this fishery is targeting spawning mackerel, this indicates that the spawning in the southern component occurs earlier each year (Punzon and Villamor, 2009). In winter 2011–2012 the timing of the spawning migration was even more pronounced in the Cantabrian Sea from early January to February compared to March and April just some years ago. However, the triennial egg survey in 2013 showed that the peak of spawning in the Cantabrian Sea was later than in both 2007 and 2010. Mackerel egg surveys also gave indication of earlier spawning for 2010 and 2013 in the western spawning component with a peak in egg production early in March compared to the earlier years when peak production was in centred on May.

Timing of overwintering, spawning migration and spawning of the NEA mackerel has previously been linked to temperature, with, e.g. earlier overwintering and spawning related to increased temperatures (Reid et al., 1997; Jansen et al., 2012; Punzón and Villamor, 2009; Jansen and Gislason, 2011). In spring and summer 2012 the measurements of plankton concentrations were among the lowest in the entire time-series since 1996 in the northern and western parts of the Northeast Atlantic.
Figure A.3.3.1. Schematic outline of the migration of the western (+ southern in top right map) adult mackerel through time. From left: late 1970s (ICES, 1990), early 1980s (ICES, 1990), latter half of 1980s (ICES, 1990), mid-1990 (Anon, 1997).

B. Data

B.1. Commercial catch

Data Compilation and Archiving

Prior to the annual assessment WG, national data submitters are responsible for submitting details of commercial catch and the associated sampling (carried out under the DCF in EU countries) to the stock coordinator. This information is supplied aggregated to ICES subarea and quarter. The data are usually detailed in an Excel spreadsheet (known as the 'exchange format'). Information on misreported catches, unallocated catches and discards can also be included on the spreadsheet. An up to date fleet description and a breakdown of catch by ICES statistical rectangle are also
requested. For nations with minor (and generally unsampled) catches, the stock coordinator will retrieve the data from the Statlant database, hosted by ICES.

Upon completion of error checking, the stock coordinator will compile the data in order that it can be used in the assessment. A key step in this process is the allocation of samples to unsampled catches. The stock coordinator will choose appropriate samples (and their relative weightings) on the basis of fleet type, quarter and geographic area. Once the samples have been assigned the stock coordinator will produce a vector of catch numbers, weights and lengths in addition to the total catch. This was traditionally done using a bespoke software application known as salloc (Patterson, 1998). Presently, a web-based data portal known as InterCatch is used which is hosted by ICES and has the advantage of acting as a central repository for the data. Frequent comparisons are made using both approaches as a quality check.

Discards

The working group has estimated the level of discards since 1978. However, this is based on estimates provided by only a few countries and is routinely identified as being an underestimate. The level of underestimation is variable and unknown.

The primary reason for the discarding or slipping (where the entire catch is released prior to being brought on board) of mackerel is on the basis of size. The discarding of high proportions of the total catch resulted in the establishment of the Cornwall box catch restrictions around the SW coat of England. Small mackerel is also often caught in the horse mackerel directed fishery, primarily in the English Channel, and is subsequently discarded either because of quota restrictions or unfavourable market conditions. Widespread discarding of fish weighing under 600 g also occurred in the early 1990s in response to the high prices paid for large fish which has been proposed as a possible reason for the low abundance of some year classes.

Data quality

If they are in possession of supplementary information, national data submitters can identify misreported catches. Often, catches will be transferred from one ICES area to another to account for information on misreporting. While not considered to be an issue in recent years, there is evidence of large-scale misreporting between ICES Sub-areas 4a and 6.a and 4.a and 2.a in the past.

A significant proportion of the complete catch time-series is considered to be of relatively poor quality in that it is believed that there is a significant underreporting of catch. A study into un accounted mortality (Simmonds, 2007) suggested significant unaccounted mortality equivalent to 1.6 to 3.4 times the reported catch. This unaccounted mortality could be the result of unreported discards and slipping, fish that escape but subsequently die or unreported catch. Improved monitoring and stricter reporting requirements have resulted in improved confidence in recent years.

B.2. Biological

B.2.1. Weighting of spawning components

The SSB estimates from the egg surveys in the North Sea and the western/southern area are used to compute the proportion of the NEA mackerel represented by each of the three spawning components. For a complete time-series of proportion of each component, see the report of the 2014 Benchmark Workshop on Pelagic Fish (ICES, 2014b) and the WGWIDE reports since then.
B.2.2. Weight-at-age in stock

The mean weights-at-age in the stock are based on available samples from the area and season of spawning of each of the spawning components.

For the southern component, stock weights are based on the samples from the Portuguese and Spanish catch taken in 8.c and 9.a in the 2nd quarter of the year, complemented by egg survey samples when available. For the Western spawning component, samples come from commercial catches, and when available, the egg survey for the areas and months corresponding to spawning (Table 2.2.1). In addition, fish sampled during the May tagging experiments by Norway in the northwest of Ireland are also included. For the North Sea spawning component, mean weights-at-age were calculated from samples of commercial catches collected from Area 4a in June combined with data collected during the North Sea egg survey in May–June when available.

The mean weights-at-age for the total stock are then calculated as weighted mean of the weights in each component, where the weighting is the egg survey based estimate of SSB in the three components. For a complete time-series on mean weights-at-age in the three components see the report of the 2014 Benchmark Workshop on Pelagic Fish (ICES, 2014b) and the WGWiDE reports since then.

Table 2.2.1. Areas and month corresponding to the core spawning used for the selection of samples to compute mean stock weights-at-age in the western component. Establish based on egg survey results (see ICES, 2014b).

B.2.3. proportions of individuals mature at age

The proportions of individuals mature at age are based on the following information:

**North Sea component:** The present proportions mature were calculated in 1984 on the basis of analysis of Norwegian biological samples from June–August 1960–1981. This revealed that 74% of the two year old mackerel, which appeared in the catches, were sexually mature. By comparing fishing mortalities for II-group mackerel with the fishing mortalities for the 3-group the year after, when they are fully recruited to the spawning stock, it seems that about 50% of the II-group mackerel are available to the fishery. Assuming that only the spawning component of the stock is available in the fishery, maturity ogive for the North Sea stock was estimated (ICES, 1984).

**Western component:** Since the 2014 mackerel benchmark (ICES, 2014b) time varying proportions of individuals mature at age are calculated based on samples from the Dutch, Irish, German and UK commercial catches collected from February to July. Proportions of mature fish at age were calculated grouping the data in blocks of five years, and moving this five year window from 1980 to the terminal year in the assessment. Due to the scarcity of samples for age 1 fish, the time varying estimate for this age is replaced by the mean across all years.

**Southern component:** Based on a histological analysis of mackerel samples collected during the 1998 Egg Survey (ICES, 2000; Perez et al., 2000).
The proportions of mature mackerel-at-age for the total stock are calculated as the mean of the proportions in the three spawning components weighted by the respective size of each component (as estimated by the egg surveys).

**B.2.4. Natural mortality and proportion of F and M before spawning**

Natural mortality (M) has been fixed at 0.15 for decades. This value was calculated based on estimates of total mortality derived from tagging data combined with catch data (Hamre, 1980). The first mackerel working group report where this value was given was 1983 (ICES, 1984).

Given the variability of the time of spawning, time varying proportions of F and M before spawning are used. The time of spawning is calculated for both the western and southern spawning component in each egg survey year as the Julian day where 50% of the total egg production has occurred. The time of spawning for the whole stock is then taken as the average of the time in these two components (weighted by their respective size). Assuming that natural mortality is constant through the year, the proportion of M occurring before spawning is equal to the proportion of the year before spawning time.

The proportion (per age group) of the catches taken before spawning time are calculated for each survey year as the sum of the quarter 1 catches plus the necessary proportion of the quarter 2 catches (if spawning time occurs in the second quarter) or as the necessary proportion of the catches in the first quarter (if spawning time occurs in the first quarter). Proportions of fishing mortality before spawning (F_{prop}) per age group are then estimated using an optimizer to find the F_{prop} value which minimizes the (square of the) difference between the observed proportion of catches before spawning, and the proportion of catches before spawning calculated based on the M_{prop} value and F at age values from the last available assessment. In order to reduce the effect of the noise in the data, average F_{prop} values are calculated by groups of age-classes: ages 1–2, ages 3–4 and ages 5 and older. F_{prop} for age 0 is by convention set to 0.

Time-series of M_{prop} and of F_{prop} at age based on linear interpolation between survey years are used as input to the assessment model. The M_{prop} and F_{prop} values of the latest survey are used for the most recent years, but these values are updated using linear interpolation when a new survey is carried out.

**B.3. Surveys**

**B.3.1. Mackerel Egg surveys (MEGS)**

Two mackerel egg surveys have been performed since 1968. Both are triennial surveys and are presently only adding new information to the time-series every third year. The Atlantic survey that started in 1977 covers the western–southern spawning grounds in the Northeast Atlantic while the other survey covers the spawning in the North Sea and Skagerrak (Figure A.3.2.1).

Each survey is split into several sampling periods covering the whole spawning area in order to get an egg production curve covering the whole spawning season. Plankton samplers currently used are Gulf 7 high speed plankton samplers or Bongo plankton nets with a mesh size of 280 μm. The Gulf samplers are open torpedo-shaped frames with a flowmeter mounted in the nosecone to measure the volume of water sampled. The Bongo’s are ringnets with 280 μm mesh size. All samplers are towed in double oblique hauls at a speed of approximately 5 knots. Next to the
plankton samples pelagic trawl samples of adult fish are collected in order to determine the sex ratio and collect ovary samples to estimate fecundity and atresia of female fish.

All eggs are sorted out from plankton samples and identified to species. The mackerel eggs in the samples are staged according to development (Lockwood et al., 1981). The stage 1 eggs are used to estimate the daily egg production per sampling period. The total annual egg production is then calculated by integrating all periods in the egg production curve. Spatio-temporal coefficient of variation (CV) of the egg production is estimated. The mackerel SSB is estimated by dividing the total annual egg production by the realized fecundity of the females and multiplying by the sex ratio. The coordination of the surveys and SSB estimation are the responsibility of the working group for mackerel and horse mackerel egg surveys (WGMEGS). Preliminary results are reported by WGMEGS to WGWIDE in the year of the survey, the results of the survey are finalized and reported in the year after the survey.

B.3.2. International Bottom Trawl Surveys (IBTS)

Observations from bottom-trawl surveys conducted between October and March from 1998 to the assessment year was compiled. Surveys conducted on the European shelf in the first and fourth quarters are collectively known as the International Bottom Trawl Survey (IBTS). All surveys sample the fish community on the continental shelf and upper shelf slope. IBTS Q4 covers the shelf from Spain to Scotland, excluding the North Sea, while IBTS Q1 covers the shelf waters from north of Ireland, around Scotland, and into the North Sea.

Trawl operations during the IBTS have largely been standardized through the relevant ICES working group (ICES, 2013). Trawling speed was generally 3.5–4.0 knots, and trawl gear is also standardized and collectively known as the Grande Ouverture Verticale (GOV) trawl. Some countries use modified trawl gear to suit the particular conditions in the respective survey areas. In some cases, the standard GOV was modified, which was not expected to change catchability significantly. However, subsequent trawls deviated more significantly from the standard GOV type, namely the Spanish BAKA trawl, the French GOV trawl, and the Irish mini-GOV trawl. The BAKA trawl had a vertical opening of only 2.1–2.2 m and was towed at only 3 knots. This was considered substantially less suitable for catching juvenile mackerel and, therefore, was excluded from the analysis. The French GOV trawl was rigged without a kite and typically had a reduced vertical opening, which may have reduced the catchability of pelagic species like mackerel. Catchability was assumed to equal the catchability of the standard GOV trawl because testing has shown that the recruitment index was not very sensitive to this assumption (Jansen et al., 2015). Finally, the Irish mini-GOV trawl, used during 1998–2002, was a GOV trawl in reduced dimensions. The reduced wingspread and trawl speed were accounted for in the model (Jansen et al., 2015).

A geostatistical log-Gaussian Cox process model (LGC) incorporating spatio-temporal correlations was used to describe the catch rates of mackerel recruits over space and time. The modelled recruitment index (square root transformed catch rate) surface in autumn year Y-1 and winter year Y was mapped every year.

The time series of spatially integrated recruitment index values are used in the assessment as a relative abundance index of mackerel at age 0 (recruits).

Data handling, modelling and post processing of the model output has been described in detail in Jansen et al. (2015).
**B.3.3. IESSNS swept-area surveys**

The main objective of the IESSNS survey in relation to quantitative assessment purposes is to provide reliable and consistent age-disaggregated abundance indices of NEA mackerel. Research vessels and chartered commercial fishing vessels from Norway (two vessels), Faroe Islands and Iceland (one from each country) were used in the Norwegian Sea and adjacent waters in July–August 2007 and from 2010 to 2013 (Nøttestad et al., 2014). In 2007, the surveys were conducted by two Norwegian vessels only. The survey aimed at covering the outer borders (zero lines) of the mackerel distribution each year from 2007 in all directions except in the southern region (south of 62°N in the North Sea). Due to the spatial expansion and increased geographical distribution of mackerel in the Nordic Seas from 2007 to 2013, the survey coverage differed from year to year in an effort to cover an expanding stock and at the same time a dynamically moving zero border lines (Figure B.3.3.1). The temporal coverage was limited to 5–6 weeks period, in order to avoid any double or zero counting during the survey. In 2011 short ship time limited the coverage in both the northern and southern part of the eastern Norwegian Sea. The swept-area survey was designed with predominantly parallel east–west survey lines, and fixed sampling stations approximately 60 nautical miles apart at predetermined geographical positions (ICES, 2013b, c; Nøttestad et al., 2014). The methodology of the survey is detailed in ICES (2013c) and Valdemarsen et al. (2014).

The catch of the different species was weighed on board and a total of 100 mackerel individuals were sampled from the catch randomly and total length (±1 cm) and whole body weight (±0.1 g) recorded from each trawl haul. The otoliths from the first 25 individuals were retrieved for age reading. On basis of the catch data and operation of the trawling hauls, swept-area estimates of age-disaggregated indices and biomass are calculated for rectangles of 2° longitude and 1° latitude across the survey area (Nøttestad et al., 2014). The results from the IESSNS surveys (Figure B.3.3.2) are reported at the working group for widely distributed stocks (WGwide) and working group for international pelagic surveys (WGips).

The decision of indices constructed and used from this survey took into account issues raised at WKPELA (ICES, 2014b) regarding apparent lower catchability of fish at age <6, variable and expanding coverage of the annual surveys, uncertainty in catch efficiency with respect to vertical distribution of the stock in the North Sea, and the fact that the survey is only covering the oceanic part of the stock leaving out mackerel further south. Thus the age-disaggregated indices constructed for analytical assessment purpose was spatially restricted to Nordic Seas, leaving out North Sea south of 62°N, delimited to age 6+ and scaled by the total area covered each year (number per square km; equivalent to cpue).
Figure B.3.3.1a–e. Average catch index (kg/km²) presented as circles ranging from no catch (a +), >1000 kg/km² to >50 000 kg/km² for NEA mackerel in July–August 2007, 2010–2013. The spatial coverage varied from 0.926 million km² in 2007 to 2.410 million km² in 2013.
Figure B.3.3a–e. Graphical representation of average catch index (kg/km²) for NEA mackerel in July–August in 2007 and 2010–2013. The spatial coverage varied from 0.926 million km² in 2007 to 2.410 million kg/km² in 2013. No catch is represented as open squares.

B.4. Commercial cpue

B.5. Other relevant data: Tagging data

Institute of Marine Research in Bergen has conducted tagging experiments with internal steel tags on mackerel since 1969, both in the North Sea and west of Ireland and the British Isles during the spawning season May–June. In the present assessment the tagging time-series was restricted to releases of the western component during the years 1977–2004 and from screening of commercial catches at factories with metal detectors from 1986–2006. During this period the same methodology was
used during both the tagging process and screening, and it was hence suggested to be a very consistent time-series. Tagging with the steel tags continued until 2009 with screening until 2010. However, a change in the fishing process from manual jigging to automatic tagging machines, which could have induced differences in post tagging mortality, as well as some uncertainty regarding screening efficiency at the factories, led to the conclusion that this part of the time-series should be excluded from the assessment. Furthermore, the new effort with tagging using RFID-technology starting in 2011 was considered to be too short, and it is expected that this time-series could be included in the assessment after further evaluation in about three years’ time.

The actual format of the tagging data used in the assessment is as numbers tagged of a year class in a specific year, the numbers recovered of this year class from that release year in all successive years, as well as the numbers screened by year class in all years.

C. Historical stock development

The assessment model

SAM

A benchmark assessment for NEA Mackerel was carried out in 2014 during the Benchmark Workshop for Pelagic Stocks (WKPELA: ICES, 2014b). Following this benchmark investigation, the tool chosen for the assessment is SAM, the state-space assessment model (Nielsen and Berg, 2014). Since 2014, this method has been implemented using the online webpage interface on www.stokassessment.org.

In SAM, the “states” (fishing mortalities and abundances-at-age) are constrained by the survival equation and follow a random walk process. The variances of the random-walk processes on abundances and fishing mortalities are parameters estimated by the model.

SAM is a fully statistical model in which all data sources (including catches) are treated as observations, assuming a lognormal observation model. The corresponding variances, so-called observation variances, are also parameters estimated by the model. Observations variances can be used to describe how well each data source is fitted in the model and effectively correspond to the internal weight given by the model to the difference data sources.

The other parameters estimated are the catchabilities of the surveys.

Uncertainties (standard errors) are estimated for all parameters and for all states (Fs and Ns).

Modifications to SAM for the NEA mackerel assessment

In the SAM mackerel assessment, tagging-recapture data from the Norwegian tagging programme are used as input data. In order to incorporate the tagging-recapture information, tag recoveries (per year and for each year class) were predicted from the model, based on the number of fish screened in the processing factories, the amount of tagged fish of the same year class released in the previous years, and the corresponding abundances of this year class in each release year estimated by the model, conditional to a post-release survival rate (time invariant and for all ages) which is a parameter estimated by the model. Given the nature of these data (count data with overdispersion) a negative binomial observation model is used.
**Assessment model configuration**

Catches for NEA mackerel for the period prior to 2000 are considered highly unreliable, due to a massive underreporting in the historical period. However, valuable information is available from other data sources (tags, egg survey) for the years before 2000. Instead of discarding all data prior to 2000, it was decided during the 2014 benchmark mackerel assessment to start the assessment in 1980, and reduce as much as possible the influence of the catches until 2000. This was done by arbitrarily down weight the catches for the years prior to 2000, by imposing a high observation variance of these catches (equal to 1.35).

Furthermore, the model incorporates tagging–recapture data until the recovery year 2006, and three survey indices: the IBTS recruitment index, the mackerel egg survey SSB index and abundances indices from the IESSNS.

More details on the input and on the survey indices incorporated in the assessment are given in the tables below (Y being the current year in which the assessment is carried out).

Due to the high uncertainty in the recruitment estimates for the terminal year, Y-1, for the NEA Mackerel, the value estimated by SAM is arbitrarily replaced by the output of RCT 3 (see short-term prediction section).

### D. Short-term projection

In a given assessment year Y, advice is given on catches for the following year Y+1 based on deterministic projections three years ahead (Y to Y+2). These projections are based on an assumption of the current year’s (also called intermediate year) catch (see section below “Assumptions for the intermediate year catch”) from which fishing mortality in the current year Y is inferred, and a range of management options for the advice year, Y+1 (fishing mortality in Y+2 being the same as Y+1), are provided.

#### Initial abundances at age

The survivors at the 1st of January of year Y estimated by SAM are used as starting abundances at age in the first year of the short-term forecast. The recruitment estimate at age 0 from the assessment in the terminal assessment year (Y-1) is considered too uncertain to be used, because this year class has not yet fully recruited into the fishery. The last (Y-1) SAM recruitment estimate is therefore replaced by predictions from the RCT3 software (Shepherd, 1997). The RCT3 software performs a linear regression between the IBTS recruitment index and the SAM estimates over the period 1998 to Y-2, and, based on this regression, predicts the Y-1 recruitment from the Y-1
IBTS index value. The final Y-1 recruitment is the average between the prediction from this regression and a time tapered geometric mean of the SAM recruitments up to Y-2, weighted by the inverse of their respective prediction standard errors. The historic performance of the IBTS index thus determines the influence of the Y-1 index value on the Y-1 recruitment produced by RCT3. A weak correlation of the survey index with the SAM estimates brings the RCT3 estimate close to the SAM geometric mean, while a strong correlation brings it close to recruitment predicted from the IBTS index for the year Y-1. The “time tapered geometric mean” is a weighted geometric mean, where the most recent years are given the highest weights.

The abundance of the survivors-at-age 1 (in Y) used as starting values for the short-term forecast is then estimated by bringing forward recruitment-at-age 0 (in Y-1) applying the total mortality-at-age 0 in year Y-1 estimated by SAM.

**Conditioning of the short-term forecast**

**Recruitment**
The recruits at age 0 in year Y, Y+1 and Y+2 are set to the geometric mean.

**Exploitation pattern**
The exploitation pattern (relative selection pattern) used in the predictions from Y to Y+2 is defined as the average of the exploitation pattern of the last three years in the assessment (Y-3 to Y-1), obtained by dividing the fishing mortalities-at-age of those three years by the value of $F_{bar4-8}$ in the corresponding years.

**Maturity-at-age, weight-at-age in the catch and weight-at-age in the stock**
The three year average of Y-3 to Y-1 is used for the proportion mature-at-age as well as stock and catch weights-at-age.

**Proportion of natural and fishing mortality occurring before spawning**
The three year average of Y-3 to Y-1 is used for the proportions $F_{prop}$ and $M_{prop}$.

**Assumptions for the intermediate year (Y)**
The catch in the intermediate year (Y) is taken as a TAC constraint. The catch is estimated from declared quotas modified by e.g. paybacks (e.g. EU COMMISSION REGULATION (EC) No 147/2007), discards (assumed to be equal to the last reported discards in year Y-1), interannual transfers and expected overcatch. Scientists from the relevant countries present at the WGWIDE each year provide the information on interannual transfers and expected overcatch.

**Management Option Tables for the TAC year**
The different management options for the catch in Y+1 are presented, covering the ICES MSY approach and ICES precautionary approach. The zero catch and constant catch options are also given for the purpose of illustration:

- **Catch** $Y+1 = \text{zero}$
- **Catch** $Y+1 = \text{TACY}$
- **$F_{bar}Y+1 = 0.22$ (Fmsy)**
- **$F_{bar}Y+1 = 0.25$ (Fpa)**
**Software implementation**

The deterministic projections are calculated in R using FLR, based on the function `stf()` from the library FLAssess. The output of the R script were compared with the output of the old ICES software MFDP and the results were found to be identical.

**E. Medium-term projections**

**F. Long-term projections**

**G. Biological reference points**

**Precautionary reference points.**

*B*<sub>lim</sub> - There is no evidence of significant reduction in recruitment at low SSB within the time-series (ICES, 2014a) hence the previous basis for B<sub>lim</sub> is retained. B<sub>lim</sub> is taken as B<sub>loss</sub>, the lowest estimate of spawning stock biomass from the revised assessment. This was estimated to have occurred in 2002; B<sub>loss</sub> = 1,840,000 t.

*F*<sub>lim</sub> - *F*<sub>lim</sub> is derived from B<sub>lim</sub> and is determined from the long term equilibrium simulations (ICES, 2014c) as the F that on average would bring the stock to B<sub>lim</sub>; F<sub>lim</sub> = 0.36.

*B*<sub>pa</sub> - The ICES basis for advice requires that a precautionary safety margin incorporating the uncertainty in actual stock estimates leads to a precautionary reference point B<sub>pa</sub>, which is a biomass reference point designed to avoid reaching B<sub>lim</sub>. Consequently, B<sub>pa</sub> was calculated as B<sub>lim</sub> * \( \exp(1.645 \sigma) \) where \( \sigma = 0.30 \) was taken as the assessment estimate of spawning biomass uncertainty in the most recent year (2013) as estimated in the 2014 management plan evaluation; B<sub>pa</sub> = 3,000,000 t.

*F*<sub>pa</sub> - *F*<sub>pa</sub> is derived from B<sub>pa</sub> and is determined from the long term equilibrium simulations as the F that on average would bring the stock to B<sub>pa</sub>; F<sub>pa</sub> = 0.25.

**MSY reference points**

MSY reference points were evaluated using equilibrium stochastic simulations (ICES, 2014c) following ICES guidelines (ICES, 2014a). Yield was considered as total catch, which is considered relevant to the situation from 2015 onwards when the fishery will be conducted under a discard ban for almost all participants.

*F*<sub>MSY</sub> - Following the ICES guidelines (ICES, 2013d WKMSYREF), F=0.22 is an appropriate F<sub>MSY</sub> target as on average it resulted in the highest mean yields with a low risk of reducing the spawning biomass below B<sub>lim</sub>.

The ICES basis for advice notes that, in general, F<sub>MSY</sub> should be lower than F<sub>pa</sub>, and MSY B<sub>trigger</sub> should be equal to or higher than B<sub>pa</sub>. Simulations indicated that potential values for MSY B<sub>trigger</sub> were below B<sub>pa</sub>. Following the ICES procedure MSY B<sub>trigger</sub> was set equal to B<sub>pa</sub>, 3,000,000 t.

1 WKMACLTMP 2014 (ICES CM 2014 / ACOM:63)
2 WKPELA 2014 benchmark assessment (ICES CM 2014 / ACOM:43)

H. Other Issues

H.1. Management plans and evaluations

The benchmark assessment performed in 2014 (WKPELA: ICES, 2014) lead to a substantial revision of the perception of the stock. The management plan adopted in 2008 has been tested on the basis of the previous assessment model. A new long term management plan evaluation was carried out in 2014 (ICES, 2014c) on the basis of the new assessment method. A range of management strategies were evaluated and a series of management options leading to maximum long-term yields combined to low probability for the stock to fall under Blim were identified. These options range from low Ftarget (0.21) combined to low Btrigger (2.0mt) to higher Ftarget (0.25) combined with higher Btrigger (3.2mt). Management options with a higher Ftarget allowed for higher yields in the short term, but lead in the long-term to a smaller stock, and were resulting a much more variable catches.

These results of this evaluation have been presented at the coastal states negotiations but no new long-term management plan has been agreed upon yet. The coastal states however consider that the management plan adopted in 2008 is no longer appropriate. Until a new management strategy is in place, ICES should give advice based on the MSY approach, in which a range of values is used for F_{MSY}.

H.2. Data limited approach for NEA mackerel

Context

In 2013 ICES was required to provide advice for the mackerel stock on the basis of no agreed quantitative assessment and corresponding management target and reference points, an exploitation rate which was potentially above the previous reference levels and no international agreement on catches.

For other stocks for which no quantitative assessment was available ICES had previously employed the WKLIFE Data Limited Stocks (DLS) approach (ICES, 2012) to provide precautionary management advice. ICES considered the DLS Method 3.2 approach, which uses survey trend based scaling of catches, applicable to the NEA mackerel. WKLIFE3 (ICES, 2013e) had evaluated the method using a simulated gadoid stock and concluded that for overexploited stocks without a defined management target, a precautionary buffer which reduced catch levels by 20% would be required to prevent increasing risk to the stock when the control rule was applied over the longer term; however caveat scenarios in which the precautionary buffer might not be required were also discussed.

ICES ACOM eventually gave advice on NEA mackerel based on a recent catch, citing the preliminary nature of the most recent egg survey, the lack of good uncertainty estimates and the lack of agreement on whether a precautionary buffer (20% reduc-
tion in catches in the first year of application) should be applied. WKLIFE3 later examined the ICES NEA mackerel advice in 2013 and made the following comment:

**“Mackerel in the Northeast Atlantic:** In the 2013 advice season, ACOM treated this stock in an ad hoc way rather than as a data-limited stock proposed by their own ADG. The rationale for this is neither adequately nor clearly explained in any ICES document. On balance, WKLIFE do not understand the rejection of the DLS guidance and support the ADG’s recommendation to treat this stock with a Category 3 method incorporating the precautionary buffer.”

As a result of the uncertainty in the application of the ICES DLS Method 3.2 to mackerel, WKPELA (ICES, 2014b) agreed that a more detailed, stock-specific evaluation of the ICES DLS Method 3.2 application to the NEA mackerel should be conducted in order to provide guidance for management advice in the event that a quantitative assessment was not available.

**NEA mackerel simulations**

WKPELA (ICES, 2014b) used a MSE simulation framework in FLR, R version 2.10.1 (2009-12-14), Core package of FLR, fisheries modelling in R. Version: 2.3-644. Flash Version: 0.7.0. Evaluations were carried out based on a simulated mackerel stock with stock dynamics (growth, recruitment, etc.), single fleet exploitation and a single fishery-independent survey index.

**Fishery–independent time–series**

WKPELA considered that the triennial egg survey index of SSB with a CV of the order of 24% gave the only, more or less complete, index of SSB (the egg survey does not include egg mortality and so it is not considered an absolute SSB estimate).

**Harvest control rule**

As the survey is carried out triennially setting the catch for three years as multi-annual advice (y+1 to y+3) is appropriate and the DLS Method 3.2 becomes:

\[
C_{y+1,y+2,y+3} = C_y \cdot Fac \quad \text{Equ. H.2.1}
\]

where Fac is derived from DLS Method 3.2 such that with \( S(y) \) the survey index in year \( y \)

\[
Fac = \left( \frac{(S(y) + S(y-1))}{2} \right) / \left( \frac{(S(y-2) + S(y-3) + S(y-4))}{3} \right) \quad \text{Equ. H.2.2}
\]

Mackerel egg survey indices are available every three years so that \( S(y-1), S(y-2) \) and \( S(y-4) \) are derived by linear interpolation from the surveys in \( S(y), S(y-3) \) and \( S(y-6) \) such that after simplification:

\[
Fac = \frac{3}{2} \cdot \left( 5S(y) + S(y-3) \right) / \left( S(y) + 7S(y-3) + S(y-6) \right) \quad \text{Equ. H.2.3}
\]

Interannual variability, which could result from noise in the survey index series, is damped by the use of an uncertainty cap, such that:

\[
\begin{align*}
\text{Fac} > 1.2 & \Rightarrow \text{Fac} = 1.2 \\
\text{Fac} < 0.8 & \Rightarrow \text{Fac} = 0.8
\end{align*}
\]

Equ H.2.4a

Equ H.2.4b

In addition to the uncertainty cap, the application of ICES precautionary buffer margin of -20% for the first application of the rule was evaluated.

\[
C_{y+1,y+2,y+3} = C_y \cdot 0.8 \cdot \text{Fac at the first application and} \quad \text{Equ H.2.5a}
\]

\[
C_{y+1,y+2,y+3} = C_y \cdot \text{Fac for subsequent iterations} \quad \text{Equ H.2.6b}
\]
DLS simulation results

Twelve scenarios were evaluated, four rule implementation options (with and without the PA buffer and the uncertainty cap) under three different stock starting conditions: historic fishing mortalities, \( F=0.22 \) (~\( F_{\text{MSY}} \)) and \( F=0.45 \) (~\( 2*F_{\text{MSY}} \)). In all cases the stock was conditioned from 1981 to 2009 and DLS management simulated to start in 2009 with first year of catch under this regime in 2010.

The performance of the DLS method was considered in the context of ICES precautionary criteria by comparing the lower 5th percentile of SSB in each forecast year with a \( B_{\text{lim}} \) proxy (\( B_{\text{lim}} \), Figure H.2.1). The inclusion of the precautionary buffer had a major influence on the likelihood that SSB had a greater than 5% probability of falling below \( B_{\text{lim}} \). In all cases in which the precautionary buffer was not applied a substantially higher percentage than 5% of the stocks fall below \( B_{\text{lim}} \) and a significant proportion collapse; the inclusion of the PA buffer appears to prevent collapse in the medium term, independent of the starting conditions in the scenarios examined. This suggests that the application of the ICES DLS Method 3.2 as simulated, using triennial egg surveys to calibrate catch set for a period of three years is precautionary when the buffer is applied; it is not without the application of the buffer.

DLS method conclusions

WKPELA (ICES, 2014b) concluded that the simulations provided very clear guidance that exploitation using the ICES DLS Method 3.2 using the triennial egg survey based on equation H.2.3 would provide precautionary management advice for the provision of triennial multiannual TAC (three years) for the NEA mackerel stock in the absence of an agreed assessment.

The application of the ICES DLS Method 3.2 to the NEA mackerel requires the inclusion of the precautionary buffer at 20% in the first year of implementation (Equation H.2.4ab) and risk of SSB<\( B_{\text{lim}} \) is also reduced by the application of the uncertainty cap at 20% in each change of three year TAC (Equ H.2.5ab).

![Figure H.2.1. Summary of NEA mackerel DLS Method 3.2 simulations in terms of ICES precautionary criteria.](image-url)

These results demonstrate that it is essential to include the precautionary buffer if the lower 5% on SSB is to be kept above the assumed \( B_{\text{lim}} \).
