ABSTRACT

'Water-soluble' fractions of fresh Kuwait crude oil, prepared by the slow-stirring method, have been examined by both fluorescence and infra-red spectroscopy. The factors governing the performance of the method and the composition of the water-extracts have been studied. A large proportion of the hydrocarbon content is present as particulate material and even the aromatic content is lowered by filtration below 1 μ m. Care in the preparation and handling of such 'water-soluble' fractions is required and the concentrations of dilutions are seldom predictable. These factors must be considered when toxicity-tests are carried out using such materials.

INTRODUCTION

The modelling in the laboratory of oil concentrations below a slick at sea is technically very difficult. Maintaining the droplet size-distribution and homogeneity of suspensions of oil during laboratory toxicity tests is similarly difficult. The use of 'water-soluble' fractions of oil has therefore been widely adopted for laboratory investigations of the biological effects of low concentrations of oil. Several methods of producing such 'water-soluble' fractions or 'water-extracts' have been described but that most widely used is the slow-stirring method of Anderson *et al.* (1974). It is recognized that the total hydrocarbon concentrations in the saturated extracts prepared by this method far exceed the theoretical true solubilities of these compounds, and that they must exist in the extract in a finely-divided, colloidal or micellular form. Indeed, some authors prefer to call such extracts 'water-accommodated' fractions.

A normal toxicity test involves the exposure of organisms to a series of concentrations of the material under test. In the case of water-extracts of oil, the final hydrocarbon concentration and composition bear an inconstant relationship to decreasing ratios of oil:water used in their preparation. Hence to prepare an extract of concentration, it is customary to dilute a saturated extract of known concentration. But if the saturated extract contains undissolved material, are the hydrocarbon concentrations of its dilutions adequately predictable and their compositions constant?

Before embarking on a series of experiments to investigate the biological effects of 'water-soluble' fractions of certain crude oils, it was therefore considered necessary to establish how reproducible the slow-stirring method was, how the aromatic and aliphatic hydrocarbons were distributed in the saturated extracts and whether such extracts were reproducibly dilutable. Preliminary results from these experiments are presented here.

METHODS

Preparation methods

In each case the slow-stirring method of Anderson et al. (1974) was used with 0.5 l of fresh Kuwait crude oil and 4.5 l of Crouch estuary sea water (approximate salinity 33.5‰) which had been filtered through Whatman GFC papers (pore size approximately 1.2 μm) but not sterilized. The filtered sea water was poured into a glass aspirator and oil from a previously unopened bottle carefully layered on to the water surface. The aspirator neck was closed but not sealed and room temperature was maintained at $19.5^{\circ} \pm 1.5^{\circ}\text{C}$. A Teflon-coated magnetic stirring bar, 6.4 cm long was used and the oil vortex held at 25% of the water column depth. Water samples were withdrawn through the aspirator tap and filtered using either slightly reduced pressure (2 x 4.7 cm diameter Whatman GFC papers) or slightly increased pressure (Gelman 0.45 μm and Nuclepore 0.2 μm membranes, both of 4.7 cm diameter). Care was taken throughout to minimize losses due to evaporation or adsorption onto surfaces. All containers were of glass and rinsed with glass-distilled grade dichloromethane before use.

Analytical methods

Samples being analysed by both fluorescence spectroscopy (UVF) and infra-red spectrophotometry (IR) were shaken before splitting. The

procedure used for UVF analysis was based on that adopted for the IGOSS project (IOC/WMO, 1976), fluorescence emission being measured at 360 nm with excitation at 310 nm. Both emission (excitation 310 nm) and synchronous ($\Delta\lambda = 25$ nm) spectra were recorded for each sample. IR analysis was similar to the method of Gruenfeldt (1973), the absorbance of the sample being measured at 2930 cm^{-1} , corresponding to the stretching frequency of C-H bands in aliphatic $-\text{CH}_2-$ groups. IR spectra were recorded for each sample between 3500 and 2500 cm^{-1} . In both cases quantification was based on the response of solutions of the fresh Kuwait crude oil used to prepare the 'water-soluble' fractions.

RESULTS

The first series of experiments was carried out to distinguish the factors governing the performance of the method, its reproducibility and the distribution of hydrocarbons in 'dissolved' or particulate form. Samples were analysed by UVF only. Any significant changes in the synchronous spectra are reported.

(i) The effect of aspirator dimensions

Three sizes of aspirator were tested, having approximate dimensions of:

Nominal capacity (l)	Internal diameter (cm)	Water column depth (cm)	Oil depth (cm)	Stirring speed (rpm)
15	24.0	10.0	1.1	140
10	20.4	13.8	1.5	150
5	16.8	21.0	2.3	180

Within the variability of the methods of preparation, extraction and analysis, there are no significant differences in aromatic hydrocarbon content between extracts from the three sizes of aspirator (Table 1). However, there is an apparent trend toward higher concentrations with increasing area of oil/water interface, although this is most pronounced in unfiltered samples and those filtered only to $< 1.2\ \mu\text{m}$. It would appear sensible to maximize the area of oil/water interface when preparing saturated extracts.

(ii) The effect of stirring time

Extracts were prepared by stirring separate batches of oil and water for different periods of time; samples were not withdrawn at successive intervals from the same batch, as this would have altered the oil:water ratio, water column depth, etc. The results (Table 2) indicate that

while less than 20 hours stirring is insufficient to produce a 'saturated' extract, greater than 40 hours stirring does not increase the aromatic hydrocarbon concentration, and may even decrease it, perhaps due to photolysis or the onset of microbial degradation. Examination of the synchronous spectra from the 0.45 μm - filtered samples showed an increase in the response with increased stirring time at 325 nm relative to that at 290 nm, indicating a change with time in the aromatic hydrocarbon composition of the extracts. A stirring time of 24-30 hours appears optimal for the preparation of saturated extracts.

(iii) The effect of separation time

It is customary to allow the water-extract to stand immobile below the oil layer before withdrawal in order to allow any oil droplets to separate upwards. Table 3a shows that there was little change in the concentration of unfiltered samples during the first 5 hours. It should be noted that at the end of the stirring period, none of the extracts throughout this series of experiments contained any droplets visible to the naked eye.

When successive samples are drawn off from the same batch of extract beneath the oil, the oil/water interface approaches the inlet and later samples can be expected to contain increasing concentrations of any rising droplets or particles. To test this, several 500 ml samples were withdrawn, with the stirrer motor still rotating into stoppered separating funnels. At the end of the separation time the lower 250 ml was drawn off. The hydrocarbon concentrations of these samples (Table 3b) were similar to those from extracts left standing under the oil, thus confirming the absence of rising droplets.

(iv) Changes due to filtration

At the end of the stirring or separation period, samples were drawn off and their hydrocarbon concentration determined in an unfiltered sample, or after passage through papers or membranes of differing pore size. The results (Table 4a) show that the aromatic hydrocarbon concentration was progressively reduced with decreasing pore size, demonstrating the importance of particulate material in the hydrocarbon content of the unfiltered extract.

To determine whether filtration reduced the aromatic hydrocarbon concentration by adsorption of 'dissolved' material on to the filter media rather than by exclusion of particulate material, 500 ml samples were passed through Whatman GFC papers of 4.7 cm or 12.5 cm diameter. The results (Table 4b) show little evidence of significantly increased adsorption by the larger papers.

To ensure reproducibility of extracts used in toxicity tests, it appears necessary to pass water extracts through a filter of pore size $\geq 0.45 \mu\text{m}$. Since the toxicity of oil extracts appears to be strongly correlated with the concentration of aromatic rather than aliphatic hydrocarbons the presence of particulate material in unfiltered water extracts raised the question of the distribution of aromatic and aliphatic hydrocarbons between 'dissolved' and particulate forms. A series of experiments was therefore carried out in which samples were divided and analysed both by UVF and IR.

(v) The distribution of aromatic and aliphatic hydrocarbons within water-extracts

Extracts were prepared in 10 l and 15 l aspirators using stirring times of 24-72 hours and separation times of 0-1 hours. Unfiltered samples ranged in concentration from 3 500-5 800 $\mu\text{g/l}$ fresh Kuwait crude oil equivalents by IR analysis, and from 650-1 000 $\mu\text{g/l}$ by UVF. There was no apparent correlation between the IR and UVF values for individual samples. This range of concentrations by IR analysis was less than the 10 040 $\mu\text{g/l}$ reported by Anderson *et al.* (1974), using a similar analytical technique.

Filtration of these extracts through $0.45 \mu\text{m}$ membranes increased the variability of the IR values (2 300-5 900 $\mu\text{g/l}$) but not of the UVF values (620-820 $\mu\text{g/l}$); again there was no correlation between the IR and UVF values. The effect of filtration was investigated further (Table 5); the results indicate that pore sizes below $1.2 \mu\text{m}$ progressively reduced the aliphatic component but had much less effect on the aromatic concentrations. It is probable that the aliphatic component is largely adsorbed to particulate material. This conclusion is supported by the IR spectra (Figure 1a), in which the 2930 cm^{-1} peak which measures the $-\text{CH}_2$ band stretch of aliphatic compounds becomes of decreasing relative importance with decreasing pore size. Even after filtration through a pore size of $0.45 \mu\text{m}$, the concentration measured by IR does not allow prediction of the concentration by UVF, or vice versa.

(vi) Dilution experiments

If the aliphatic concentrations of filtered extracts vary so much, are dilutions reproducible and thus suitable for toxicity tests? To test this, saturated water-extracts were prepared and filtered through $0.45 \mu\text{m}$ membranes. This 'neat' extract was serially diluted with $1.2 \mu\text{m}$ filtered sea water whose hydrocarbon concentration ranged from 9-13 $\mu\text{g/l}$

aromatics and from 20-70 $\mu\text{g}/\text{l}$ aliphatics, but on one occasion the concentrations were 26 and 270 $\mu\text{g}/\text{l}$ respectively. The dilution series was as follows:

	Nominal concentration of 'neat' extract
416 ml of 'neat' extract made up to 1 000 ml: (Dilution 1)	0.416
304 ml of dilution 1 made up to 1 000 ml: (Dilution 2)	0.126
664 ml of dilution 2 made up to 2 000 ml: (Dilution 3)	0.042
608 ml of dilution 3 made up to 2 000 ml: (Dilution 4)	0.013

The remainder of each dilution was divided and solvent-extracted for either IR or UVF analysis. In Table 6 the predicted values are calculated from the dilution of each successive measured concentration, taking into account the hydrocarbon concentration of the sea water used in each case. The results show that the initial dilution usually produced an aromatic and aliphatic concentration well below that predicted. Thereafter, the aromatic concentration, though usually lower than predicted, was more predictable than the aliphatic which tended to be well above the predicted value. This could be explained if part of the hydrocarbon content of the 'neat' extract is unstable, perhaps held in an 'accommodated' form by high concentrations of some non-hydrocarbon compound derived from the oil. When sufficient diluting water is added, the concentration of this compound falls below a critical level and the concentration of hydrocarbons that can be held in this 'accommodated' form falls, forcing the excess to form particulates which adsorb to the container walls.

Alternatively, the addition of 'clean' particulates in the diluting water (filtered only $< 1.2 \mu\text{m}$) could sweep both aromatics from 'solution' and aliphatics from suspension, followed by adsorption to the container walls. It is important to note that when samples were split for analysis by IR and UVF, the solvent extractions could not be carried out in the original sample containers and hence would not include material adsorbed to the sample container walls. Adsorption to the walls would deplete not only the initial, but to a lesser extent all subsequent dilutions explaining the lower-than-predicted aromatic concentrations. However, such a process would not account for the often much higher-than-predicted aliphatic concentrations, unless aliquots were occasionally taken from liquid rich in particulates derived from the walls, even though the containers were shaken beforehand.

The IR spectra showed a progressive increase in the peaks at 2 960 cm^{-1} (due to the $-\text{CH}_3$ band stretch) and at 3 030 cm^{-1} (due to the $-\text{CH}$ band stretch in aromatic compounds) relative to that at 2 930 cm^{-1} until by the final dilution they became the dominant peaks (Figure 1b). It appears that dilution progressively removes aliphatic compounds, which again would be explained by adsorption to the container walls of the particulates on which they are held. There was no marked change in peak height distribution from the 'neat' extract to the first dilution despite the great change in concentration; the UVF spectra remained the same throughout the dilution sequence.

DISCUSSION

Aspirator dimensions and stirring time affect the concentration and composition of the unfiltered 'saturated' sea water extract of Kuwait crude oil, but allowing the extract to stand below the oil layer makes little difference over the first 5 hours. Even with fixed aspirator dimensions and stirring time, the concentration of aromatic and aliphatic hydrocarbons in the unfiltered extract varies considerably. Filtration through a pore size of $\approx 0.45 \mu\text{m}$, achieves reasonably reproducible concentrations of aromatic, but not aliphatic hydrocarbons. The latter are present mainly in particulate form and, even after filtration, serial dilution of extracts does not produce the predicted reductions in the concentrations of aliphatic hydrocarbons. When serially diluted, the initial dilution of the 'neat' extract gives lower than predicted concentrations of aromatic hydrocarbons. The hydrocarbon composition of serially diluted extracts changes progressively until very low concentrations (2-5 x background) consist almost entirely of aromatic hydrocarbons with benzenoid compounds becoming increasingly important. Thus, evaluation of the toxicity of such extracts and dilutions requires a thorough analysis of each test-concentration and comparisons can be made only between concentrations of the same hydrocarbon composition.
