Report to the Working Group on Pollution Baseline and
Monitoring Studies in the Oslo Commission and ICNAF Areas
on Heavy Metals in Selected Finfish and Shellfish from the

Northwest Atlantic

Preface

As noted in the preface to Annex 6, Document C.M.1976/E:4 the conduct of large-scale baseline sampling programmes is often fraught with difficulties. Much of the data reported in the present paper were collected prior to the establishment of a standard ICES monitoring program and associated protocol. Fortunately, however, the data reported were the result of standardized analyses conducted by two laboratories^{1/} of the National Marine Fisheries Service, National Oceanic and Atmospheric Administration. Both of these laboratories participated in the 1975 ICES trace metal intercalibration exercise sponsored by ICES (Annex 5a, Document C.M.1976/E:4). The general methods used are also outlined in Annex 5a.

Introduction

The species of fish reported upon will differ from those in Annex 6 although a few species are common both to the eastern and western Atlantic. Generally, however, the species reported upon in this paper represent the same families or "feeding types" as those from the eastern Atlantic which are considered in Annex 6.

The data in the present paper include the results of analyses for cadmium, copper, lead, mercury and zinc as well as chromium, arsenic, silver, nickel and molybdenum. In some cases, a species of fish was analyzed for all or most of these metals. In other instances, however, a particular species or tissue was run for only a few metals or even a single metal. This was especially true for mercury, a metal which has been of some concern to scientists, politicians and the general public in the United States. We have attempted to use the same format for reporting the data as was used in Tables 1 and 2 of Annex 6. We have, however, placed both muscle and liver data in the same table rather than separating the data into two separate tables as in Annex 6. This was done so that data on different tissues from the same fish samples could be more readily compared.

The geographic locations where fish and shellfish samples were taken are given in column 1 (source) of each table and shown on Figure 1. The date of collection is given for most samples; no collections were made prior to March 1971. In most instances, the length of fishes is provided rather than the year-class information.

All metal concentrations are given as parts per million (ppm), wet weight. The final column of Table 1 indicates the source of the data presented. Where a broken or dashed line (---) is inserted in the table, it indicates that those particular data are unavailable;

^{1/} Environmental Chemistry Investigation, Milford Laboratory, Northeast Fisheries Center, National Marine Fisheries Service, Milford, Connecticut 06460; and Southeast Utilization Research Center, National Marine Fisheries Service, College Park, Maryland 20740

generally, this is the case where an analysis was run on a composite sample and only a single or mean value for a particular metal was available. When 0.000 appears in the table, it means that the measurement was attempted but the values obtained were below the minimum detection levels used in the particular analysis.

Results of the Baseline Heavy Metal Survey

As previously noted, the data herein reported were collected prior to the development of a standard ICES protocol. In many cases, however, the data were collected in a fashion similar to the optimal program; at least 10 individuals were taken during summer months. Unfortunately, as indicated in Annex 6, "theoretical biological practicalities" are often not the same as "actual biological practicalities" and this paper therefore contains the same potential sources of variations as did data in Annex 6. However, most of the data are the results of analyses which were conducted in a way similar to the analyses which were provided for the ICES intercalibration exercise. Moreover, the data obtained from R. Greig, Milford Laboratory, National Marine Fisheries Service, have been verified through intercalibration exercises using neutron activation techniques (Greig, 1975). We therefore have confidence that the reported data are representative of the species considered and the areas from which they were collected.

The results of the survey are given in Tables 1-52 and are discussed in some further detail below. The area covered by the survey is shown in Figure 1. The dotted lines show the boundaries of specific ICNAF areas off the east coast of North America. Lettered and numbered boxes or grid squares indicate sampling localities referred to in the tables under sources.

Metal Analyses

As was the case with monitoring data provided in Annex 6, certain species were more intensively studied than others. Also, as previously noted, the analyses were particularly concerned with certain metals and less so with others. Again, however, all data are provided. An extensive compilation of data from a far larger data set than that reported herein is presently underway and should be available as a report to ICES prior to October 1977; these data are being computer processed and are therefore not available for the present study.

As was done in Annex 6, comparisons between data in the present study as well as between these data and those in Annex 6 were made on the basis of mean concentrations in each sample. Generally, almost all heavy metal data in the present study were within the same general ranges observed for mean metal concentrations reported in Annex 6. For instance, Annex 6 reported a range of mean concentrations of mercury in cod muscle and liver tissue samples of 0.02-0.32 mg/kg and 0.01 to 0.09, respectively; the present study showed a range of mean concentrations for cod muscle and liver of 0.07-0.25 and 0.02-0.11 mg/kg.

Likewise, cod samples from ICNAF areas off the east coast of North America ranged from 0.94-4.64 mg/kg in zinc concentration while cod reported upon in Annex 6 had 1.9-7.3 mg/kg zinc in muscle tissue. Concentrations of other metals, including copper, cadmium and lead, followed similar patterns. The upper means for muscle from cod reported upon in Annex 6 usually were slightly elevated relative to those considered here; present values were from fish collected in areas E and F off Cape Cod, Massachusetts (see Fig. 1).

The data for other gadids such as haddock showed similar or lower values when compared with those given in Annex 6 for cod. Mean metal concentrations in silver, red and white hake could not be compared in detail because of the limited metal analyses accomplished for silver hake. However, mean mercury values in muscle tissues from silver hake were comparable to values from the white and red hakes from North America as well as the "hake" reported on in Annex 6.

Comparisons of metal concentrations in plaice and sole reported upon in Annex 6, with similar data for yellowtail flounder and winter flounder provided in the present report, again indicate generally similar values in these species of fish. The upper mean concentrations of mercury tended to be higher in the plaice and sole (0.26 and 0.32 mg/kg) contrasted to yellowtail and winter flounder (0.12 and 0.19 mg/kg). Upper mean values of zinc were, however, lowest in the yellowtail flounder, 4.57 mg/kg, and highest in the winter flounder, 16.0 mg/kg. Plaice and sole had upper mean values of 6.1 and 6.5 mg/kg, respectively.

The present compendium considers a number of species which are taxonomically or ecologically quite different from the species reported upon in Annex 6. Because of the ease in catching them, their catholic diet and possible commercial utilization, particularly large numbers of elasmobranchs were taken. The spiny dogfish was taken at stations from the Canadian-United States boundary south to Cape Hatteras. When fish in the general size range of 70-95 cm were compared, it was observed that fish taken close to shore and in the southern portions of the aforementioned area may have tended towards higher mean mercury values in muscle tissues. Additional specimens must be obtained and analyzed, however, before any conclusions can be drawn. Such collections should be made in a highly systematic manner in order to be able to compare specific species, of well-defined size ranges, taken from precisely located collecting sites or areas.

The bluefish is a common inshore marine species which will move into embayments, such as Chesapeake Bay, to forage. These fish and similar species which move through both estuaries and inshore coastal waters and feed in the water column may be particularly suitable for monitoring studies. They tend to integrate the effects of exposure to a wide range of environments and are also large, dominant predators in many food webs. Thus, they are likely to show accumulations of specific contaminants if these are in the environments through which they pass and live in. The bluefish analyzed and reported on in the present paper had quite high muscle mercury values with the maximums in some individual fish being close to the 0.5 mg/kg "action levels" established by the United States Government. Some cusk also had muscle tissue mercury values approaching the action levels. Another dominant apex predator, the white marlin, had high mercury values in muscle tissue. A mean of 0.545 mg/kg was measured in this species with a maximum value of 1.140 mg/kg.

This study also reports on metals measured in commercially important invertebrates (Tables 46-52). Values for metals in various tissues of crabs, lobsters, oysters, hard shell clams, scallops and squid are given. Somewhat elevated values for mercury and cadmium were measured in digestive gland tissue from the rock crab (Table 47b).

Discussion

Until objective computer analyses are done considering species, feeding types, geographic area(s) habituated, and other factors, it will continue to be difficult to arrive at definite conclusions in regard to body burdens of metals and other contaminants in closely or distantly related species collected over broad geographic areas. The data reported in this paper, as well as those in Annex 6, form the beginning of a baseline against which spatial and temporal changes can be compared. The need for such

comparisons becomes apparent when samples of similar-sized individuals are collected over a wide geographic range. For instance, analyses of the surf clam, Spisula solidissima, over a range from Virginia to Long Island, New York, show that individuals taken from the New York Bight apex (source area II) are characterized by higher tissue heavy metal levels (Wenzloff et al., 1977).

Personnel of the Northeast Fisheries Center are presently analyzing large amounts of heavy metal data to determine the relationships between sources of heavy metals and elevated tissue or body burdens in resources and forage species. It is also important to understand the relevance of these findings. Of what significance are increased levels of metals in tissues, i.e. elevated body burdens, to the resource species in question? There is relatively little known in this regard (George and Coombs, 1975; Young and Jan, 1977) but it is essential to understand the impact of metals on resources if they, and their environment, are to be effectively managed. Several authors (Vernberg and Vernberg, 1972; Bryan and Hummerstone, 1973; and Jones, Jones and Radlett, 1976) have noted that metal burdens may affect metabolism in various ways and, further, may play a role in complex synergisms which are poorly understood.

Conclusions

Other than mercury, none of the samples contained mean levels of metals which exceeded values which are presently acknowledged to be harmful from the human consumption point of view. Some individual demersal species, such as the dogfish, and the apex predator, marlin, did individually contain levels of mercury which exceed recognized "action levels". There were possible relationships between size of fish, geographic area of catch, species or feeding type and metal values. There has not, however, been sufficient analysis of the data to definitely confirm these relationships.

In several instances mean values for specific species reported upon in the present paper were very similar to values reported for the same or similar species in Annex 6.

Finally, scientists working within the National Marine Fisheries Service are presently preparing a much more extensive data base, which is being analyzed using computer techniques, to verify possible relationships between heavy metal values in resources and other factors such as geographic areas of catch, size and age of fish and date of catch.
